(54) Abstract Title

Processor having multiple program counters and instruction registers

(57) Consecutive program words are stored alternately in memories 1A, 1B which are addressed by program counters 2A, 2B to provide outputs to instruction registers 3A, 3B. An instruction decoder 4 is controlled to select an instruction from the registers in turn for execution by circuit 5C. This arrangement enables branch instructions to be processed quickly. Embodiments may include decoder bypass paths (7A, 7B, Figure 11) or a double-length-instruction decoder (4N, Figure 13).

PROCESSOR HAVING MULTIPLE INSTRUCTION REGISTERS

The present invention relates to a processor that may be a micro processing unit (MPU) with an internal or external program memory, a digital signal processor (DSP) with an internal or external program memory or the like.

These types of processors perform pipeline processing in order to speed up processing. In pipeline processing in the prior art, an instruction queue comprising, for example, 6 stages of registers is connected to the front stage of a decoder and a queue with the same number of stages is connected to the rear stage of this decoder. Since, when the pipeline has settled into the stationary state, one normal instruction can be executed in one cycle, high-speed processing is possible.

However, with instructions that require processing different from that in normal instructions, such as branch instructions, immediate data transfer instructions or variable length instructions, the processing speed is reduced as described below.

(1) In the case of a branch instruction, since it changes the execution sequence of the instructions, instructions that have been partially processed have been discarded and it is necessary to start anew from the

instruction fetch, cancelling out the benefits of the pipeline processing.

Therefore, branch prediction may be performed for the branch instruction by connecting the instruction at the branch destination in front of the branch instruction and reading it into the pipeline. However, this induces the structure of the compiler, which performs the branch prediction, complicated. Also, under certain conditions the branching will not occur, and since the instruction at the branch destination will still be executed, though it is not necessary, the processing speed is reduced.

Another approach eliminates dead time by inserting the instruction to be executed before a conditional branch instruction in rear of the conditional branch instruction as a delay slot and by executing this delay slot while the branch destination is being determined. However, this method too, induces the compiler that inserts the delay slot more complicated and also, if a delay slot cannot be inserted, the processing speed is reduced.

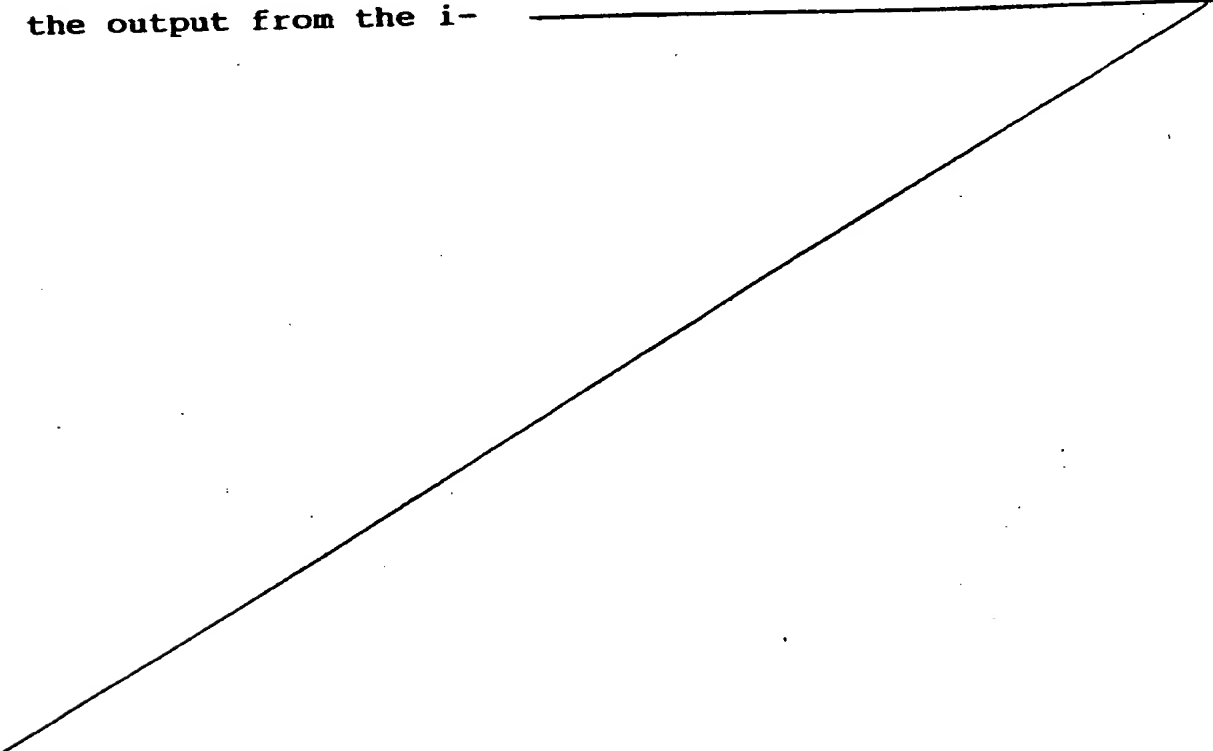

(2) In the case of an immediate data transfer instruction, time is required for the calculation of execution address and for memory access. This problem can be overcome and processing can be speeded up by using an immediate data transfer instruction which places the data inside an instruction word. However, since an immediate data

transfer instruction must wait for the intake of the immediate data, the execution needs a plurality of cycles, thus reducing the processing speed.

(3) In the case of multiple length instructions, it is necessary to perform decoding again after the multiple lengths are compounded, thus the execution needs a plurality of cycles, reducing the processing speed.

Accordingly, an object of the present invention is to provide a processor which can speed up the processing without complicating the compiler.

In accordance with the invention, there is provided a processor comprising for each i that is 1 to n : an i -th program counter; i -th memory means for being addressed with the output from the i -

th program counter; and an i-th instruction register for holding the outputs from the i-th memory means; the processor further comprising: an instruction decoder for selecting one of the outputs from the 1-st to n-th instruction registers and for decoding the selected output; an execution circuit for executing processing based upon the output from the instruction decoder; and a control circuit for inducing the instruction decoder to select the outputs from the 1-st to n-th instruction registers sequentially, for inducing the i-th program counter to update after the output of the i-th instruction register is selected by the instruction decoder, and for inducing the i-th instruction register to hold the outputs of the i-th memory means after the update; wherein a program is stored in the 1-st to n-th memory means in units of one word in the order of the 1-st memory means to the n-th.

With the _____ invention, since the branch instruction and the instruction at the destination of branch are executed continuously without interruption and without the compiler performing any special processing for the branch instruction, it is possible to speed up the processing compared to the prior art without complicating the compiler.

In accordance with a preferred first mode of _____

_____ the present invention, there is

provided the processor according to the invention wherein the outputs of the 1-st to n-th instruction registers are supplied to input terminals of the execution circuit via corresponding 1-st to n-th bypasses; and the control circuit decides whether or not the instruction decoded by the i-th instruction decoder is an immediate data transfer instruction based upon the output of that decoder and, if it is determined to be an immediate data transfer instruction, induces the execution circuit to fetch the immediate data through the i-th bypass in order to execute the immediate data transfer instruction at once.

With the first mode, an immediate data transfer instruction is executed in one cycle without interruption, achieving faster processing in comparison with the prior art, which requires a plurality of cycles.

In accordance with a preferred second mode of the present invention, the processor according to the invention further comprises: a multiple length instruction decoder for instructions of length N, where $2 \leq N \leq n$, for decoding N successive words in the outputs of the 1-st to n-th instruction registers as a multiple length instruction and for supplying the decoding result to the execution circuit; wherein the control circuit, when the output of one of the 1-st to n-th instruction decoders indicates a multiple length instruction of length N, induces the multiple length instruction decoder to decode the multiple length instruction of length N, and induces the said one of the instruction decoders to decode the instruction following after _____

the multiple length instruction of length N.

With the second mode, a multiple length instruction of length N is executed in one cycle without interruption, achieving faster processing in comparison with the prior art which requires a plurality of cycles.

FIG. 13 is a block diagram showing a processor in the sixth embodiment according to the present invention.

Referring now to the drawings, wherein like reference characters designate like or corresponding parts throughout several views, embodiments of the present invention are described below.

First embodiment

FIG. 1 shows a processor in the first embodiment according the present invention.

The memory 1A and the memory 1B have an identical structure with equal storage capacity and one program is

stored in the two memories 1A and 1B by dividing the program into one word units which are written alternately into each of the two memories. Namely, with the addresses in the memory 1A designated as A0, A1, A2, ... and with the addresses in the memory 1B designated as B0, B1, B2, the program is stored in the order: A0, B0, A1, B1, A2, B2,

The address input terminal of the memory 1A is connected to the output terminal of the program counter 2A via exclusive wires and the address input terminal of the memory 1B is connected to the output terminal of the program counter 2B via exclusive wires. Each of the program counters 2A and 2B has a two stage structure consisting of the normal counter unit, which is the input stage, and the holding (register) unit which is the output stage and, as explained later, the contents PAN which have been updated and confirmed at the input stage, is held at the output stage as PA in response to a control signal.

The data output terminal of the memory 1A is connected to the input terminal of the instruction register 3A via exclusive wires and the data output terminal of the memory 1B is connected to the input terminal of the instruction register 3B via exclusive wires. The memory 1A constantly supplies the contents IA1 at the address PA specified by the program counter 2A to the input terminal of the instruction

register 3A and the memory 1B constantly supplies the contents IB1 at the address PB specified by the program counter 2B to the input terminal of the instruction register 3B. The instruction registers 3A and 3B hold IA1 and IB1 respectively, to output them as IA2 and IB2 respectively in response to a strobe signal.

The output terminals of the instruction registers 3A and 3B are connected to the input terminals of the instruction decoders 4A and 4B respectively. Each of the instruction decoders 4A and 4B is provided with an internal register at the input stage and decodes the instruction code held in this register for output as DA or DB.

The output terminals of the instruction decoders 4A and 4B are connected to the input terminals of the execution circuit 5 and the control circuit 6. The execution circuit 5 is provided with a selector at the internal input stage, which selects either DA or DB in response to the selection control signal, and a register that holds the selected DA or DB. Based upon the decoding result, which is the output of the decoder, held in this register, the execution circuit 5 executes processing such as calculation or data transfer in the same manner as an execution circuit in the known art, which is provided with an ALU and internal registers. To simplify the expression, we proceed on the premise that selection either DA or DB means selection either DA or DB

and holding it in the register.

These components 1A to 4A, 1B to 4B and 5 operate in accordance with control signals sent from the control circuit 6. These control signals are generated in synchronism with the double phase clocks CA and CB as shown in FIG. 2. The basics of the control performed by the control circuit 6 are as follows:

(1) The control circuit 6 induces the execution circuit 5 to select and execute DA and DB alternately, supplies the selection control signal to the execution circuit 5 with the timing of the rise of the clock CA and induces it to select DB when it has completed the execution of the output of the instruction decoder 4A and induces it to select the decoding result DA when it has completed the execution of the decoding result of the instruction decoder 4B. Then it induces the internal register to hold these decoding result. The initial selection after a reset is DA.

(2) When DA is selected, the control circuit 6 induces the instruction decoder 4A to hold IA2 and when DB is selected, it induces the instruction decoder 4B to hold IB2.

(3) When IA2 is held in the instruction decoder 4A, the control circuit 6 induces the instruction register 3A to hold IA1 and when IB2 is held in the instruction decoder 4B, it induces the instruction register 3B to hold IB1.

(4) The control circuit 6 induces the contents PAN or

PBN at the input stage of the program counter 2A or 2B to be held at the output stage as PA or PB with the timing of the rise of the clock CA.

(5) The control circuit 6 induces IA1 to be held in the instruction register 3A or IB1 to be held in the instruction register 3B with the timing of the rise of the clock CB.

(6) The control circuit 6 updates the contents PAN or PBN at the input stage of the program counter 2A or 2B with the timing of the rise of the clock CB. Updating of PAN is usually performed by supplying one pulse to the clock input terminal of the program counter 2A to add one to the counter value, but when the output of the instruction decoder 4A indicates an unconditional branch instruction, is performed by determining the address of the branch destination based upon the output of the instruction decoder 4A and then by loading it to the program counter 2A, and when the output of the instruction decoder 4A indicates a conditional branch instruction, is performed by determining the address of the branch destination based upon the output of the instruction decoder 4A and a status flag and then by loading it to the program counter 2A. The updating of the program counter 2B is executed in the same manner as that of the program counter 2A.

(A) Next, the normal pipeline processing that is

performed after the processor is reset until the processor enters the stationary state is explained in reference to FIG. 2.

The starting address for program execution after a reset is designated as n . Although not shown in FIG. 1 or FIG. 2, when the processor is reset, initializing processing is performed in which n is loaded to the input stages of the program counters 2A and 2B and, On the other side, the execution starting address n is supplied to the input terminals of the memory 1A and 1B through another route(not shown).

The rise points in time of the clock CA are assigned odd numbers; t_1, t_3, t_5, \dots and the rise points in time of the clock CB are assigned even numbers; t_2, t_4, t_6, \dots . In addition, IA_1 , which is read out from the address 1 in the memory 1A is indicated as $IA_1(i)$, and IA_2 when $IA_1(i)$ is held in the instruction register 3A is indicated as $IA_2(i)$. The same rule applies to IB_1 and IB_2 . In the following explanation, the pipeline has 5 stages, consisting of the instruction fetch (IF) stage, the instruction decode (ID) stage, the execution (EX) stage, the memory access (MA) stage and the stage of writing to register (WB). For example, in the case of an instruction with which data are read out from the memory address that is the content of the index register IX with 100 added, to load to the register R;

i.e.,

LOAD R, IX + 100;

the EX stage is the processing in which 100 is added to the contents of the index register IX to determine the execution address. the MA stage is the processing in which data are read out from this execution address in the memory and the WB stage is the processing in which the data that have been read out are stored in the register R. In the case of an instruction as to register-register operation such as a register-register compare instruction, EX stage is the operation between two registers. MA stages is meaningless and WB stage is the storing the result of the operation in a register. In the case of an immediate data transfer instruction; i.e.,

LDI R, 200

, WB stage is the processing in which an immediate data 200 are stored in the register R, and EX and MA stages are meaningless.

Of the control signals output from the control circuit 6, those shown in FIG. 2 are as follows: the instruction IA decode signal is for inducing the instruction decoder 4A holding IA2, to decode it when it is at high and the instruction IB decode signal is for inducing the instruction decoder 4B holding IB2, to decode it when it is at high. The instruction IA execution signal is for inducing the

execution circuit 5 to select and execute DA when it is at high and the instruction IB execution signal is for inducing the execution circuit 5 to select and execute DB when it is at high. IF stage starts from the updating of PA or PB of the program counter 2A or 2B.

(t1) n is loaded to both the program counters 2A and 2B. $PA=n$ and $PB=n$. The instruction decoders 4A, 4B and the execution circuit 5 are in the wait state.

(t2) $IA1(n)$ and $IB1(n)$ are held in the instruction registers 3A and 3B respectively. One pulse is supplied to the clock input terminals of the program counters 2A and 2B so that $PAN=n+1$ and $PBN=n+1$. The instruction decoders 4A, 4B and the execution circuit 5 are in the wait state.

(t3) $IA2(n)$ and $IB2(n)$ are held in the instruction decoders 4A and 4B respectively and decoded. $PA=n+1$ and $PB=n+1$. The execution circuit 5 is in the wait state.

(t4) $IA1(n+1)$ and $IB1(n+1)$ are held in the instruction registers 3A and 3B respectively. One pulse is supplied to the clock input terminals of the program counters 2A and 2B so that $PAN=n+2$ and $PBN=n+2$. The execution circuit 5 is in the wait state.

(t5) $DA(n)$ is selected by the execution circuit 5 and executed to perform EX stage. On the other side, $DB(n)$ is not selected and the instruction decoder 4B enters the wait state. This wait state means the output of the instruction

decoder 4B is not used with outputting the decoding result.
IA2(n+1) is held in the instruction decoder 4A and decoded.
PA = n + 2.

(t6) IA1(n+2) is held in the instruction register 3A.
One pulse is supplied to the clock input terminal of the
program counter 2A so that PAN = n + 3.

(t7) DB(n) is selected by the execution circuit 5 and
executed. DA(n+1) is not selected and the instruction
decoder 4A enters the wait state. The memory access which
corresponds to DA(n) is executed by the control circuit 6.
IB2(n+1) is held in the instruction decoder 4B and decoded.
PB = n + 2.

(t8) IB1(n+2) is held in the instruction register 3B.
One pulse is supplied to the clock input terminal of the
program counter 2B so that PBN = n + 3.

(t9) DA(n+1) is selected by the execution circuit 5
and executed. DB(n+1) is not selected and the instruction
decoder 4B enters the wait state. The write to register
that corresponds to DA(n) and the memory access which
corresponds to DB(n) are executed by the control circuit 6.
IA2(n+2) is held in the instruction decoder 4A and decoded.
PA = n + 3.

The five-stage normal pipeline processing is executed
in the manner described above and the operation enters the
stationary state.

(B) Now, the pipeline processing for an unconditional branch instruction that is executed after the processor enters the stationary state is explained in reference to FIG. 3.

We proceed on the premise that this unconditional branch instruction is stored at address A_n (address n in the memory 1A), that a relative branch destination address K is in the word of the unconditional branch instruction and that the relative branch destination address K is an even number $2k$ and is in memory 1A.

The actual branch destination for the relative branch destination address K is determined in the same manner as with a processor in the prior art, in which the memory 1A and the memory 1B are integrated, by regarding address i in the memory 1A as $2i$ and also regarding the address i in the memory 1B as $2i+1$ for each i that is 0 to M . To put it more concretely, when the unconditional branch instruction is stored in the memory 1A (or the memory 1B) and K is an odd number $2k+1$, i.e., when the lowest-order bit of K is "1", the branch destination relative address is equal to the branch destination relative address k in the memory 1B (or the memory 1A) and when K is an even number $2k$, i.e., when the lowest-order bit of K is "0," the branch destination relative address is equal to the branch destination relative address k in the memory 1A (or the memory 1B).

The following is an explanation having part of the pipeline processing of an instruction word preceding the address $n-1$ in the memory 1A and preceding the address $n-1$ in the memory 1B.

(t1) $DA(n-2)$ is selected by the execution circuit 5 and executed. On the other side, $DB(n)$ is not selected and the instruction decoder 4B enters the wait state. $IA2(n-1)$ is held in the instruction decoder 4A and decoded. $PA=n$.

(t2) The unconditional branch instruction $IA1(n)$ is held in the instruction register 3A. One pulse is supplied to the clock input terminal of the program counter 2A so that $PAN=n+1$.

(t3) $DB(n-2)$ is selected by the execution circuit 5 and executed. On the other side, $DA(n-1)$ is not selected and the instruction decoder 4A enters the wait state. $IB2(n-1)$ is held in the instruction decoder 4B and decoded. $PB=n$.

(t4) $IB1(n)$ is held in the instruction register 3B. One pulse is supplied to the clock input terminal of the program counter 2B so that $PBN=n+1$.

(t5) $DA(n-1)$ is selected by the execution circuit 5 and executed. On the other side, $DB(n-1)$ is not selected and the instruction decoder 4B enters the wait state. $IA2(n)$ is held in the instruction decoder 4A and decoded. $PA=n+1$.

(t6) $IA1(n+1)$ is held in the instruction register 3A.

It is determined by the control circuit 6 that $DA(n)$ indicates an unconditional branch instruction and the k of the relative branch destination address $K=2k$ which is contained in $DA(n)$ is loaded to the program counters 2A and 2B so that $PAN=k$ and $PBN=k$. With this, the subsequent operation becomes identical to the operation after a reset.

(t7) $DB(n-1)$ is selected by the execution circuit 5 and executed. On the other side, $DA(n)$ is not selected and the instruction decoder 4A enters the wait state. $IB2(n)$ is not held in the instruction decoder 4B (is cancelled). $PA=k$ and $PB=k$.

(t8) $IA1(k)$ and $IB1(k)$ are respectively held in the instruction registers 3A and 3B. $PAN=k+1$ and $PBN=k+1$.

(t9) The decoding result $DA(n)$ of the unconditional branch instruction is selected by the execution circuit 5 and executed without meaning. This is because k has been loaded into the program counters 2A and 2B at the time $t6$, thus the execution of the unconditional branch has been performed. $IA2(k)$ and $IB2(k)$ are held in the instruction decoders 4A and 4b respectively and decoded. $PA=k+1$ and $PB=k+1$.

(t10) $IA1(k+1)$ and $IB1(k+1)$ are held in the instruction registers 3A and 3B respectively. $PAN=k+2$ and $PBN=k+2$.

(t11) $DA(k)$ is selected by the execution circuit 5 and

executed. On the other side, $DB(k)$ is not selected and the instruction decoder 4B enters the wait state. The memory access which corresponds to $DA(n)$ is executed without meaning by the control circuit 6 (the MA stage corresponding to $DA(n)$ is meaningless). $IA2(k+1)$ is held in the instruction decoder 4A and decoded. $PA = k + 2$.

As has been explained, since the unconditional branch instruction and the instruction at the branch destination are executed continuously without any interruption, a delay in processing is prevented. Although FIG. 3 illustrates the case in which the branch destination is A_k , a delay in processing is prevented in a similar manner when the branch destination is B_k .

(C) Next, the pipeline processing for a conditional branch instruction that is executed after the processor enters the stationary state is explained in reference to FIG. 4.

The following discussion is based on the premise that a register-register compare instruction is stored at address A_n , that the conditional branch instruction is stored at address B_n and that the branch destination address is determined to be either A_{n+1} or B_k depending upon the result of the execution of this compare instruction in EX stage.

In FIG. 4, the operation from the time point t_1

through the time point t_7 is obvious from the above explanation in reference to FIGS. 2 and 3, and it is, therefore, omitted here. The time points t_3 to t_7 correspond to the time points t_1 to t_5 in FIG. 3.

(t8) It is determined by the control circuit 6 that $DB(n)$ is a conditional branch instruction. With this decision, the k of the relative branch destination address $K = 2k$, which is contained in $DB(n)$, is loaded to the program counter 2B so that $PBN = k$. Then $k + 1$ is loaded to the program counter 2A as the address following the Bk so that $PAN = k + 1$. With this, the subsequent operation becomes similar to that performed after a reset.

(t9) The decoding result $DA(n)$ of the compare instruction is selected by the execution circuit 5 and executed. On the other side, $DB(n)$ is not selected and the instruction decoder 4B enters the wait state. $IA2(n+1)$ is held in the instruction decoder 4A and decoded. $PB = k + 1$ and $PB = k$.

(t10) $IA1(k+1)$ and $IB1(k)$ are held in the instruction registers 3A and 3B respectively. One pulse is supplied to the clock input terminals of the program counters 2A and 2B so that $PAN = k + 2$ and $PBN = k + 1$.

(t11) With the result of the execution of the compare instruction described above, the branch destination of the conditional branch instruction is determined. In FIG. 4, the

branch destination address is determined to be B_k and $DA(n+1)$ is cancelled. The decoding result $DB(n)$ of the conditional branch instruction is selected by the execution circuit 5 and executed formally. The memory access that corresponds to $DA(n)$ is executed without meaning by the control circuit 6 (the MA stage corresponding to $DA(n)$ is meaningless). $IA_2(k+1)$ and $IB_2(k)$ are held in the instruction decoders 4A and 4B respectively and decoded. $PB = k + 1$.

(t12) $IB_1(k+1)$ is held in the instruction register 3B. $PBN = k + 2$.

(t13) The decoding result $DB(k)$ of the instruction at the branch destination is selected by the execution circuit 5 and executed. On the other side, $DA(k+1)$ is not selected and the instruction decoder 4A enters the wait state. The write to register that corresponds to $DA(n)$ and the memory access that corresponds to $DB(n)$ are executed without meaning by the control circuit 6 (the WB stage corresponding to $DA(n)$ and the MA stage corresponding to $DB(n)$ are meaningless). $IB_2(k+1)$ is held in the instruction decoder 4A and decoded. $PA = k + 2$.

As has been explained, since the conditional branch instruction and the instruction at the branch destination are executed continuously without any interruption, a delay in processing is prevented. Although FIG. 4 illustrates a

case in which the branch destination is Bk. a delay in processing is prevented in a similar manner when the branch destination is Ak.

Second embodiment

FIG. 5 shows a processor in the second embodiment according to the present invention.

In this processor, in order to supply the immediate data at the second word in an immediate data transfer instruction directly to the execution circuit 5A from the instruction registers 3A and 3B, the output terminals of the instruction registers 3A or 3B are directly connected to the input terminals of the execution circuit 5A via the bypass 7A and 7B respectively.

When the control circuit 6A determines that the output of the instruction decoder 4A or 4B indicates an immediate data transfer instruction, it induces the execution circuit 5A to directly hold IA2 or IB2 via the bypass 7A or 7B and to execute it in one cycle.

All other aspects are identical to those of the processor shown in FIG. 1.

FIG. 6 shows the pipeline processing for the immediate data transfer instruction after the processor has entered the stationary state.

We proceed on the premise that the first word of the

immediate data transfer instruction is stored at the address A_n and that the immediate data, i.e., the second word of the immediate data transfer instruction, are stored at the address B_n .

(t1) $DA(n-2)$ is selected by the execution circuit 5A and executed. On the other side, $DB(n-2)$ is not selected and the instruction decoder 4B enters the wait state. $IA2(n-1)$ is held in the instruction decoder 4A and decoded. $PA = n$.

(t2) The unconditional branch instruction $IA1(n)$ is held in the instruction register 3A. One pulse is supplied to the clock input terminal of the program counter 2A so that $PAN = n + 1$.

(t3) $DB(n-2)$ is selected by the execution circuit 5A and executed. On the other side, $DA(n-1)$ is not selected and the instruction decoder 4A enters the wait state. $IB2(n-1)$ is held in the instruction decoder 4B and decoded. $PB = n$.

(t4) The immediate data $IB1(n)$ is held in the instruction register 3B. One pulse is supplied to the clock input terminal of the program counter 2B so that $PBN = n + 1$.

(t5) $DA(n-1)$ is selected by the execution circuit 5A and executed. On the other side, $DB(n-1)$ is not selected and the instruction decoder 4B enters the wait state. $IA2(n)$ is held in the instruction decoder 4A and decoded.

$PA = n + 1$.

(t6) $IA1(n+1)$ is held in the instruction register 3A.
 $PAN = n + 2$. The control circuit 6A determines that $DA(n)$ indicates an immediate data transfer instruction and therefore, that $IB2(n)$ is immediate data.

(t7) Based upon the above determination, $IB2(n)$ is not held in the instruction decoder 4B but is held in the internal register of the execution circuit 5A via the bypass 7B. $DB(n-1)$ is selected by the execution circuit 5A and executed. $DA(n)$ is not selected and the instruction decoder 4A enters the wait state. $PB = n + 1$.

(t8) $IB1(n+1)$ is held in the instruction register 3B.
 $PBN = n + 2$.

(t9) The decoding result $DA(n)$ of the immediate data transfer instruction is selected and executed without meaning by the execution circuit 5A (the EX stage corresponding to $DA(n)$ is meaningless). $IA2(n+1)$ and $IB2(n+1)$ are held in the instruction decoders 4A and 4B respectively and are decoded. $PA = n + 2$ and $PB = n + 2$.

(t10) $IA1(n+2)$ and $IB1(n+2)$ are held in the instruction registers 3A and 3B respectively. $PAN = n + 3$.

(t11) $DA(n+1)$ is selected by the execution circuit 5A and executed. On the other side, $DB(n+1)$ is not selected and the instruction decoder 4B enters the wait state. The memory access that corresponds to $DA(n)$ is executed

without meaning by the control circuit 6A (the MA stage corresponding to DA(n) is meaningless). IA2(n+2) is held in the instruction decoder 4A and decoded.

The data transfer of an immediate data to a register is executed in the WB stage corresponding to DA(n).

As has been explained so far, the double length immediate data transfer instruction which includes immediate data is executed without interruption in one cycle, preventing any delay in processing.

Third embodiment

FIG. 7 shows a processor in the third embodiment according to the present invention.

In order to execute a double length instruction faster, this processor is provided with a double length instruction decoder 4N in addition to the instruction decoders 4A and 4B. The output terminals of the instruction registers 3A and 3B are connected to the input terminals of the double length instruction decoder 4N, and the output terminal of the double length instruction decoder 4N is connected to the input terminal of the execution circuit 5B. The double length instruction decoder 4N is provided with a register that holds IA2 and IB2 at its internal input stage and decodes double length instructions held in this register.

When the control circuit 6B decides that the output of

the instruction decoder 4A or 4B indicates a double length instruction, it induces the double length instruction decoder 4N to hold IA2A and IB2 and induces it to decode the double length instruction. The decoding of the double length instruction is executed in one cycle.

All other aspects are identical to those of the processor shown in FIG. 1.

FIG. 8 shows the pipeline processing for a double length instruction when the processor has entered the stationary state.

In FIG. 8, the double length decode signal is for the execution circuit 6B to induce the double length instruction decoder 4N to hold IA2 and IB2 and decode them when it is at high.

We proceed on the premise that one double length instruction is stored at the addresses An and Bn. Since the operation at the time points t1 to t5 is identical to that at the time points t1 to t5 in FIG. 3, its explanation is omitted here.

(t6) IA2(n+1) is held in the instruction register 3A. PAN=n+2. The control circuit 6B determines that DA(n) indicates the first word of the double length instruction.

(t7) DB(n-1) is selected by the execution circuit 5B and executed. Based upon the decision described above, IA2(n) and IB2(n) are held at the input stage of the double

length instruction decoder 4N and decoded. On the other side.

after this holding, $IA2(n+1)$ is held in the instruction decoder 4A, and decoded. $PA=n+2$ and $PB=n+1$.

(t8) $IA1(n+2)$ is held in the instruction register 3A and $IB1(n+1)$ is held in the instruction register 3B. $PAN=n+3$ and $PBN=n+2$.

(t9) The decoding result of the double length instruction decoder 4N is selected by the execution circuit 5B and executed. $IA2(n+1)$ is held in the instruction decoder 4A and is decoded. $PB=n+2$.

(t10) $IB1(n+2)$ is held in the instruction register 3B. $PBN=n+3$.

(t11) $DA(n+1)$ is selected by the execution circuit 5B and executed. On the other side, $DB(n+1)$ is not selected and the instruction decoder 4B enters the wait state. The memory accesses that correspond to $DA(n)$ and $DB(n)$ is executed by the control circuit 6B. $IA2(n+2)$ is held in the instruction decoder 4A and decoded. $PA=n+3$.

As has been explained so far, the double length instruction is executed without interruption in one cycle, thus preventing a delay in processing.

Fourth embodiment

FIG. 9 shows the processor in the fourth embodiment according to the present invention.

In this processor, in order to simplify the structure compared to that shown in FIG. 1, only one instruction decoder 4 is used. Since there is only one instruction decoder 4, the input stage inside the execution circuit 5C is not provided with a selector and instead a selector which selects either the output of the instruction register 3A or 3B is provided at the next stage of the register located at the input stage within the instruction decoder 4. The only difference between the execution circuit 5C and the execution circuit 5 shown in FIG. 1, is that the execution circuit 5C is not provided with a selector at the internal input stage. The only difference between the instruction decoder 4 and the instruction decoder 4A shown in FIG. 1, is that the instruction decoder 4 is provided with the selector at the internal input stage.

Since there is only one instruction decoder 4, the control performed by the control circuit 6F is simpler than that performed by the control circuit 6 shown in FIG. 1. When IA2 is held in the instruction decoder 4, the control

circuit 6F adds one to the PAN and induces the instruction register 3A to hold IA1. When IB2 is held in the instruction decoder 4, the control circuit 6F adds one to the PBN and induces the instruction register 3B to hold IB1.

All other aspects of this processor are identical to those of the processor shown in FIG. 1.

The normal pipeline processing that is performed after the processor is reset and until the processor enters the stationary state is explained in reference to FIG. 10. The initializing processing not shown in the figure that is executed immediately after a reset is identical to that performed in the first embodiment described earlier.

(t1) $PA=n$ and $PB=n$. The instruction decoder 4 and the execution circuit 5C are in the wait state.

(t2) $IA1(n)$ and $IB1(n)$ are held in the instruction registers 3A and 3B respectively. $PAN=n+1$ and $PBN=n+1$.

(t3) $IA2(n)$ is held in the instruction decoder 4 and is decoded. $IB2(n)$ enters the wait state. $PA=n+1$. The execution circuit 5C is in the wait state.

(t4) $IA1(n+1)$ is held in the instruction register 3A. $PAN=n+2$.

(t5) $DA(n)$ is held by the execution circuit 5C and executed. $IB2(n)$ is held in the instruction decoder 4 and decoded. $PB=n+1$.

(t6) $IB1(n+1)$ is held in the instruction register 3B.

$PBN = n + 2$.

(t7) $DB(n)$ is executed by the execution circuit 5C. The memory access that corresponds to $DA(n)$ is executed by the control circuit 6F. $IA2(n+1)$ is held in the instruction decoder 4 and decoded. $PA = n + 2$.

(t8) $IA1(n+2)$ is held in the instruction register 3A. $PAN = n + 3$.

(t9) $DA(n+1)$ is executed by the execution circuit 5C. The memory write that corresponds to $DB(n)$ and the write to register that corresponds to $DA(n)$ are executed by the control circuit 6F. $IB2(n+1)$ is held in the instruction decoder 4 and decoded. $PB = n + 2$.

The normal pipeline processing with 5 stages is executed in the manner described above and the processor enters the stationary state. Since the pipeline processing for an unconditional branch instruction and a conditional branch instruction executed after the processor enters the stationary state can be easily understood from the earlier explanation, its explanation is omitted here. With this processor too, the advantage that has been described already, that an unconditional branch instruction and a conditional branch instruction can be executed without interruption in one cycle, is achieved.

Fifth embodiment

FIG. 11 shows the processor in the fifth embodiment according to the present invention.

This processor is a simplified version of the structure shown in FIG. 5, having incorporated a similar simplification to that shown in FIG. 9. Namely, in order to directly supply the immediate data at the second word of an immediate data transfer instruction to the execution circuit 5D from the instruction registers 3A or 3B, the output terminals of the instruction registers 3A and 3B are directly connected to the input terminals of the execution circuit 5D via the bypass 7A and 7B respectively.

FIG. 12 shows the pipeline processing for an immediate data transfer instruction that is executed after the processor enters the stationary state. The conditions for the immediate data transfer instruction are the same as those in the case in FIG. 6.

(t1) $DB(n-2)$ is held by the execution circuit 5D and executed. $PA=n$. $IA2(n-1)$ is held in the instruction decoder 4 and decoded.

(t2) $IA1(n)$ is held in the instruction register 3A.
 $PAN=n+1$.

(t3) $DA(n-1)$ is held by the execution circuit 5D and executed. $IB2(n-1)$ is held in the instruction decoder 4 and decoded. $PB=n$.

(t4) $IB1(n)$ is held in the instruction register 3B.

$PBN = n + 1$.

(t5) $DB(n-1)$ is held by the execution circuit 5D and executed. The immediate data transfer instruction $IA2(n)$ is held in the instruction decoder 4 and is decoded. $PA = n + 1$.

(t6) $IA1(n+1)$ is held in the instruction register 3A so that $PAN = n + 2$. The control circuit 6G decides that $IA2(n)$ is an immediate data transfer instruction and, therefore, that $IB2(n)$ is immediate data. The control circuit 6G controls to send $IB2(n)$ as immediate data to the execution circuit 5D via the bypass 7B.

(t7) The decoding result $DB(n)$ of the immediate data transfer instruction is executed without meaning by the execution circuit 5D. The memory access that corresponds to $DA(n)$ is executed without meaning by the control circuit 6G. $IA2(n+1)$ is held in the instruction decoder 4 and is decoded. $PB = n + 1$.

(t8) $IB1(n+1)$ is held in the instruction register 3B. $PBN = n + 2$.

(t9) $DA(n+1)$ is executed by the execution circuit 5D. The memory access that corresponds to $DA(n)$ is executed without meaning by the control circuit 6G. $IB2(n+1)$ is held in the instruction decoder 4 and decoded. $PA = n + 2$.

The data transfer of a double length immediate data to a register is executed in the WB stage corresponding to $DA(n)$.

As has been explained so far, since the double length immediate data transfer instruction that includes immediate data is executed without interruption in one cycle, a delay in processing is prevented.

Sixth embodiment

FIG. 22 shows the processor in the sixth embodiment according to the present invention.

This processor is a simplified version of the structure shown in FIG. 7, having incorporated a similar simplification to that shown in FIG. 9. Namely, in order to execute a double length instruction faster, a double length instruction decoder 4N is added to the structure shown in FIG. 9 in addition to the instruction decoder 4, and the output terminals of the instruction registers 3A and 3B are connected to the input terminals of the double length instruction decoder 4N via the wires 8A and 8B respectively and the output terminal of the double length instruction decoder 4N is connected to the input terminal of the execution circuit 5E.

Since the operation performed by the control circuit 6H of this processor can be easily understood from the earlier explanation, its explanation is omitted here. With this processor too, the advantage described earlier, that a double length instruction can be executed without

interruption in one cycle is achieved.

CLAIMS:

1. A processor comprising for each i that is 1 to n :
an i -th program counter;
 i -th memory means for being addressed with the output

from said i-th program counter; and

an i-th instruction register for holding the outputs from said i-th memory means;

said processor further comprising:

an instruction decoder for selecting one of the outputs from said 1-st to n-th instruction registers and for decoding the selected output;

an execution circuit for executing processing based upon the output from said instruction decoder; and

a control circuit for inducing said instruction decoder to select the outputs from said 1-st to n-th instruction registers sequentially, for inducing said i-th program counter to update after the output of said i-th instruction register is selected by said instruction decoder, and for inducing said i-th instruction register to hold the outputs of said i-th memory means after said update;

wherein a program is stored in said 1-st to n-th memory means in units of one word in the order of said 1-st memory means to said n-th.

2. A processor according to claim 1 wherein:

the outputs of said 1-st to n-th instruction registers are supplied to input terminals of said execution circuit via corresponding 1-st to n-th bypasses; and

said control circuit decides whether or not the instruction decoded by the i-th instruction decoder is an immediate data transfer instruction based _____

upon the output of that decoder and, if it is determined to be an immediate data transfer instruction, induces said execution circuit to fetch the immediate data through the i-th bypass in order to execute the immediate data transfer instruction at once.

3. A processor according to claim 7, further comprising:

a multiple length instruction decoder for instructions of length N, where $2 \leq N \leq n$, for decoding N successive words in the outputs of said 1-st to n-th instruction registers as a multiple length instruction and for supplying the decoding result to said execution circuit;

wherein said control circuit, when the output of one of the 1-st to n-th instruction decoders indicates a multiple length instruction of length N, induces said multiple length instruction decoder to decode said multiple length instruction of length N, and induces the said one of the instruction decoders to decode the instruction following after said multiple length instruction N.

4. A processor substantially as herein described with reference to and as shown in Figures 9 and 10, 11 and 12 or 13 of the accompanying drawings.
